COMP1021
Introduction to Computer Science

Handling of Data Types

David Rossiter and Gibson Lam

Outcomes

- After completing this presentation, you are expected to be able to:
  1. Explain the various data types in Python
  2. Write code to check the data types of variables
  3. Convert between some of the data types

Data Types in Python

- Data types mean the ‘type’ of things that you store inside variables
- For example, if you run this line of code:

```
mynumber = 5
```

  we say that the variable has an integer data type because it stores an integer value (5)
- Usually you don’t need to worry about data types because Python automatically determines the type when you create a variable

Data Types You Have Used So Far

- You have used the following data types in the course so far:
  - Numbers
    - Integers, e.g. `1` and `5` (=numbers with no decimal place)
    - Floating point numbers or floats, e.g. `1.2` and `3.14` (=numbers with a decimal place)
  - Collections
    - Lists, e.g. `[1, 0, 2, 1]`
    - Tuples, e.g. `(200, 100)`
    - Strings, e.g. `"I am a piece of text!"`
  - Booleans, i.e. `True` or `False`

Knowing the Data Type You Use

- You can use the `type` command to give you the data type currently used by a variable
- Here are some examples:

```
>>> number_of_dogs = 1
>>> type(number_of_dogs)
<class 'int'>
>>>
>>> age_of_my_dog = 1.5
>>> type(age_of_my_dog)
<class 'float'>
>>>
>>> name_of_my_dog = "Toffee"
>>> type(name_of_my_dog)
<class 'str'>
```

An integer

A float

A string

More Data Types

```
>>> i_am_a_frog = False
>>> print(type(i_am_a_frog))
<class 'bool'>
>>>
>>> my_dogs = ["Toffee", "Popcorn", "Jelly"]
>>> print(type(my_dogs))
<class 'list'>
>>>
>>> dog_data = (10, 34, 1.5)
>>> print(type(dog_data))
<class 'tuple'>
>>>
```

A Boolean

A list

A tuple

Checking Data Type

- Sometimes it is useful to make sure the data type is correct before you run some code
- Here is an example function `double()`

Checking the data type of variable `x`

```
def double(x):
    if type(x) == int or type(x) == float:
        return 2 * x
    else:
        print("Hey, give me a number!")
```

- The function doubles any given number but prints an error if the input `x` is not a number

Running the Example

- You can run the function in the previous slide with different input values

```
>>> double(5)
10
>>>
>>> double(7.2)
14.4
>>>
>>> double("Hello?")
Hey, give me a number!
>>>
>>> double([2000])
Hey, give me a number!
>>>
```

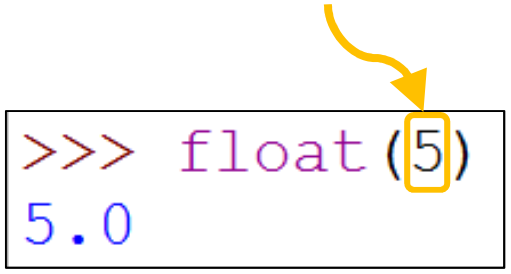
Data Type Conversion

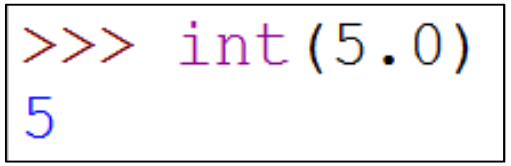
- Some Python code may have a different meaning when it is used with different data types
- For example, using ‘+’ on numbers means addition, using ‘+’ on strings means ‘gluing’ the text together
- Some code may generate errors when the correct data type is not being used
- Because of that, you have to make sure the data types are correct before the data is used
- That is when you may need *data type conversion*

Converting Between Numeric Data Types

- We have used two types of numeric data: integers and floating point numbers
- To convert from an integer to a floating point number you use the `float()` function
- To convert from a floating point number to an integer you use the `int()` function

Python thinks a number is an integer if it doesn't have a decimal point; otherwise it's a float





Storing as an Integer or a Float

- For a numeric value 5, Python displays it as '5' when it is stored as an integer
- For the same value 5, Python displays it as '5.0' when it is stored as a float

The number is stored as an integer

The number is stored as a float

```
>>> number = int(5)
>>> print(number)
5
>>> number = float(5)
>>> print(number)
5.0
```

Converting from Numbers to Strings

- When you need to display a number you typically need to convert the number to a string before you can put the number together with other text, i.e. using '+'
- To do that you use the `str()` function to convert a number to a string, for example:

```
>>> age = 25
>>> print("I am " + str(age) + " years old!")
I am 25 years old!
```

Using print()

- `print()` is clever, it can print almost anything
- For example:

```
print("Just like 1 + 1 is", 2, \
      "my heart for you is", True)
```

```
Just like 1 + 1 is 2 my heart for you is True
```

- Some functions, e.g. `turtle.write()`, are not so clever, as shown on the next page

Using turtle.write()

- If we do this using `turtle.write()`:

```
import turtle
turtle.write("Just like 1 + 1 is", 2, \
             "my heart for you is", True)
```

```
Traceback (most recent call last):
...
    item = self.cv.create_text(x-1, -y, text = txt, anchor = anchor[align],
KeyError: 'my heart for you is'
>>>
```

- You can only join the things before writing:

```
turtle.write("Just like 1 + 1 is " + str(2) + \
             " my heart for you is " + str(True))
```

Converting From Strings to Numbers

- You can use the `int()` function or the `float()` function to convert a string to an integer or a floating point number respectively
- For example, you need to do that when you ask a user for number input using the `input()` function
- Here is an example:

```
>>> age = input("How old are you? ")
How old are you? 25
>>>
>>> age = int(age)
>>> print("You look like a " + str(age * 2) + "-year-old to me!")
You look like a 50-year-old to me!
```

Possible Problem When You Convert a Number to an Integer

- You need to be careful when you convert a string to an integer
- You will get an error if the string contains a decimal point, like this:

```
>>> age = "2.5"
>>> age = int(age)
Traceback (most recent call last):
  File "<pyshell#53>", line 1, in <module>
    age = int(age)
ValueError: invalid literal for int() with base 10: '2.5'
```

A Safer Approach

- A safer approach to convert a string to an integer is:
  - First, convert the string to a floating number
  - Then, convert the floating number to an integer
- Here is an example:

```
>>> age = "2.5"
>>> age = int(float(age))
>>> print(age)
2
```

When a Float is Converted to a String

- Sometimes the result may not be what you expect when converting a number to a string
- For example, if the number is stored as a floating point number you will have a decimal place in the resulting string

```
>>> age = 25.0
>>> print("I am " + str(age) + " years old!")
I am 25.0 years old!
```

Because there is a '.0' at the end it means this is a floating point number
